## **LONG-TERM GOAL**

The long-term goal of my work in sediment acoustics is to develop a physically meaningful model to describe geoacoustic wave propagation in marine sediments on the basis of a set of primitive physical variables.

## **OBJECTIVES**

The principal scientific objective of my work has been to develop a mathematical model that is able to predict wave velocity and attenuation in the sediments found near the seafloor. Specifically, the model has been designed to accept as input parameters certain fundamental primitive variables, such as grain size, porosity, grain density and gas content that are directly related to the geological processes producing the wide range of sediments that are encountered in the world's oceans. A number of auxiliary technological objectives have also arisen in the course of our work related to remote sensing and in-situ measurement of sediment geoacoustic properties. One of these objectives has been to develop a set of tools that allow the measurement of velocity and attenuation as well as certain related geotechnical variables such as shear strength and cone penetration resistance in the sediment column. These measurements provide the "ground truth" for assessing the validity and usefulness of the basic geoacoustic model and have important applications in other areas such as mine burial prediction and the evaluation of sonar records..

## **APPROACH**

My approach has been to develop a theoretical geoacoustic model based on the classical Biot theory for porous, fluid-filled media. The model reflects the influence of variables such as porosity and overburden pressure and includes several kinds of intrinsic attenuation that are important in different kinds of ocean sediment. We have performed extensive field and laboratory experiments aimed at determining appropriate input parameters as well as checking the validity of the model predictions. Much of our earlier work is described in the monograph "Sediment Acoustics" (Stoll, 1989). More recent progress, especially the results of extensive field work, has been described in a series of technical papers and is being incorporated into several new chapters in a second edition of the monograph to be published in the near future. Over the past several years we have participated in a number of field experiments in cooperation with other investigators such as T. Akal at SACLANT Undersea Research Center in LaSpezia, Italy and M. Richardson at the Naval Research Laboratory, Stennis Space Center. During this work several new testing techniques were developed to measure in-situ properties of the sediments immediately beneath the seafloor including p-wave velocity and attenuation, shear wave velocity and attenuation for both vertically and horizontally polarized wave

motion, and undrained shear strength based on quasistatic cone penetration tests. In addition, sediment cores taken at many sites were analyzed to obtain porosity, grain size distribution and other fundamental properties, the objective being to establish the ground truth at each test location and develop correlations between such quantities as in-situ shear wave velocity, undrained shear strength and porosity.

In addition to the field work mentioned above, a new series of laboratory experiments has been initiated for the purpose of studying the dispersion that occurs during p-wave propagation in granular sediments as one moves from the “low frequency” regime to the “high frequency” range that is currently of considerable interest. The purpose of this work is to help in the evaluation of some of the new propagation models that are being proposed to explain the penetration of acoustic energy into the seafloor at low grazing angles observed in recent experiments. Some of these new models that are based largely on high frequency data, and in some cases idealized scattering models, do not properly account for the dispersion that would normally be expected in going from low to high frequencies and therefore may be questionable for applications in the general case.

## WORK COMPLETED

In the fall of 1999 our research team, which includes R. Stoll and I. Bitte from Lamont-Doherty Observatory and R. Flood from the Marine Research Lab, SUNY, Stony Brook, carried out field experiments in the Gulf of Mexico near Ft. Walton Beach, Florida as part of the ONR SAX99 experimental program. These experiments which were part of the ONR High Frequency Acoustics DRI, were aimed at establishing a baseline model valid over a somewhat wider frequency range than the main high frequency experiments and to see if velocity dispersion as predicted by the Biot theory would play an important role in interpretation of the SAX99 experimental results. Our main objective was to measure p-wave velocity in the same portion of the sediment column ( upper few meters) but at significantly lower frequencies than those generated in the bulk of the high frequency work. To accomplish this we used the arrival times of shallow diving waves at 12 equally spaced receivers using the classical Weichert, Herglotz, Bateman inversion scheme illustrated in this figure.

*P-wave velocity versus depth  
obtained by Weichert, Herglotz,  
Bateman analysis of first arrivals  
and wave trajectories  
corresponding to different ranges*

As a result of work during FY00 and FY01 analysis of the data from this experiment has been largely completed and we submitted a paper to the Journal of the Acoustical Society of America describing the results. This paper has been reviewed and is now in press. In addition Stoll attended the ONR high frequency acoustics workshop in Lyon, France in the summer of 2000 and an ONR meeting at Stennis Space Center in January 2001 to present the results of our work and review the overall accomplishments of the SAX 99 experiments.

In the lab, we have been modifying test equipment to allow more extensive acoustic testing of granular sediments in the low frequency range. To accomplish this we have created an experimental setup wherein a cylindrical column of sediment is confined in a thick-walled container and driven by piston in the 0-mode frequency range in order to measure the phase difference over the length of a specimen subjected to carefully controlled end conditions.

## **RESULTS**

Analysis of our field data shows that there is pronounced velocity dispersion that occurs in uniform, unconsolidated sands in the intermediate frequency range (typically between 500 Hz and 10 kHz). This dispersion, which is one of the most striking predictions of the Biot theory, has important implications when interpreting bottom-penetrating sonar records (Maguer et al, 2000) as well as when choosing attenuation values for geoacoustic modeling purposes. Our results suggest that the historical method of cataloging attenuation as a single value valid at 1kHz and then assuming that the attenuation varies as (or nearly as) the first power of frequency can lead to poor estimates when extrapolating to a different frequency range. Moreover, our results also demonstrate that a linear viscoelastic model, based on an assumed relaxation function that leads to attenuation varying as the first power of frequency, is not adequate for describing the response of marine sediments such as unconsolidated sand.

## **IMPACT/APPLICATION**

While our primary interest has been to model geoacoustic properties of the sediment, a number of tools developed for our field work have direct applications to other areas of interest to the Navy such as mine burial prediction. As an example, the penetration resistance measured by several different types of probe we have developed is directly related to the bearing capacity of the sediment which is of prime importance in studies of mine burial in the seafloor. These probes include an expendable bottom penetrometer, "XBP", a modified version of the "STING" penetrometer and a quiaistatic penetrometer that measures both cone and sleeve penetration resistance to a depth of 2 meters into the sea floor. The XBP probes have been used to map critical areas in two recent NATO exercises aimed at "Rapid Environmental Assessment" (Stoll and Akal, 1999).

## **TRANSITIONS**

In 1999 we prepared an XBP (expendable bottom penetrometer) evaluation package for the Naval Oceanographic Office composed of software, an electronics interface board and a users manual for use on board NAVO ships. As a result of their initial trials of the XBP they ordered eight additional systems for use on their survey vessels and on Navy mine hunting ships. These systems were completed and delivered in July, 2001.
